HYDROLOGIC IMPACT OF SALVAGE LOGGING IN
THE TROUT CREEK WATERSHED NEAR PENTICTON, B.C.

J.D. Cheng
Forest Hydrologist
Hydrology Section

May 1981

ABSTRACT

This study was conducted to assess the hydrologic effects of salvage logging necessitated by a mountain pine beetle infestation within the Trout Creek Basin of the Okanagan Valley in south central B.C.

After making some necessary assumptions and using available regional streamflow data, the USFS water yield increase analysis procedure was applied to estimate streamflow changes in Camp Creek, a tributary to Trout Creek, after salvage logging in its watershed. The results indicate that increases of 3.5, 13.9, 14.8, 3.8 and 0.8 percent respectively can be expected for the mean annual, March, April, May and August flows in Camp Creek after the 1977-79 logging. These increases would become 6.6, 22.3, 24.9, 7.2 and 2.5 percent respectively after the completion of additional salvage logging in 1981. Although these results cannot be substantiated due to the lack of comparable streamflow data from a nearby unlogged control watershed, they probably represent the relative order of streamflow changes which are likely to take place. The estimated streamflow changes are small at this initial stage of salvage logging but as the extent of forest removal dictated by mountain pine beetle attacks increases in the future, the flow regime alteration may reach a scale significant to water management operations. The lack of quantitative channel stability survey data prevents a meaningful calculation of allowable annual timber removal for the Camp Creek watershed. On the other hand, field observations indicate that the degree and extent of ground disturbance associated with the salvage logging as presently

evident in the study watershed is not very likely to cause significant erosion and stream sedimentation problems.

This study suggests that the USFS water yield increase analysis procedure could be a useful operational tool in assessing the impact of logging on some aspects of streamflow for watersheds with adequate input data. Improvements to the analysis procedure, such as the capability of assessing changes in late summer low flow as well as daily and instantaneous peak flows should be attempted as part of its future development by specialists in soils, forestry and hydrology. The usefulness of the USFS water yield increase analysis procedure for application in B.C. can be assured and greatly enhanced only if a well-designed province-wide field data collection program is implemented to provide the required input data. With proper application of the analysis procedure, it should be possible to place the operational forestry-related water management problems and their solutions in a better perspective.

1. INTRODUCTION

In the Trout Creek Basin of the Okanagan Valley and other areas in south central and southwestern British Columbia (B.C.), the mountain pine beetle has recently become a major factor in determining the extent of logging operations in terms of the location and volume of annual cut (Figure 1). This is partly due to the present policy of the B.C. Ministry of Forests to salvage as much infested timber as possible.

Because of the importance of Trout Creek to the water supply needs of the City of Summerland, a major concern of the B.C. Water Management Branch and the water users is the hydrologic consequences of this salvage logging with respect to detrimental changes in water yield and flow regime. The purpose of this study is to evaluate the hydrologic effects of salvage logging on a mountain pine beetle-affected tributary watershed, Camp Creek watershed, within the Trout Creek Basin (Figures 1 and 2). This study was requested by the Water Management Branch of the B.C. Ministry of Environment in Victoria. The major efforts of this study are placed on the potential effects of salvage logging on water yield and flow regime. The impacts of this salvage logging on erosion and water quality are only briefly discussed based on observations made during one field trip in August, 1979. To estimate the potential changes in water yield and flow regime as a result of the watershed salvage logging, this study makes use of the U.S. Forest Service (USFS) water yield increase analysis procedure (Isacson, 1977; Russell, 1971; Hetherington, 1978). The selection of the Camp Creek

watershed for this assessment is based on 1) its long record of stream-flow (1965 to present) which is essential for the application of USFS water yield increase analysis procedure, and 2) its high percentage (13%) of watershed area already salvage-logged between 1977 and 1979, with additional logging over 8.6% of the watershed by 1981.

The limitations of the methodology used in this report are discussed and suggestions for improvement are made. The water and forest management implications of the results presented in this study for the Trout Creek Basin in particular and the Okanagan Valley generally are briefly discussed.

2. WATERSHED AND STREAMFLOW CHARACTERISTICS

Camp Creek watershed, located in the headwater area of the Trout Creek Basin (Figures 1 and 2) has a drainage area of 13.1 mi², (above gauging station 08NM134) rising from 3260 to 6200 feet with a median elevation of 4770 feet (Table 1). The elevation distribution of the total watershed area is included in Table 2. The watershed slopes are mostly gentle to moderate gradient with an average of 122 feet per mile or 2.3% (Reksten 1974). The watershed is underlain almost equally by intrusive rocks of paleozoic to tertiary and of middle to late jurassic. Coarse-textured soils such as sandy loams and gravelly sandy loams are characteristic of the watershed.

The major forest types at the lower elevations of the watershed are ponderosa pine, lodgepole pine, and Douglas-fir occurring in single

or mixed types. According to information provided by the B.C. Ministry of Forests, the total area cleared by salvage logging and the B.C. Hydro powerline right-of-way from 1977 to July, 1979 is 1,087 acres, occurring at various elevations with the majority below 5,000 feet. In other words, approximately 13 percent of the total watershed is bared of forest cover as a result of timber harvesting. The elevation distribution of these 1977-79 logged areas relative to total watershed area is shown in Table 2. Additional logging planned for 1979 is scheduled for completion by 1981. The elevation distribution of the accumulated 1977-81 logged area is presented in Table 3. At the end of 1981, the total logged areas will be 1,813 acres or 21.6 percent of the total watershed area.

Based on available streamflow data collected at the hydrometric station near the watershed outlet, (08NM134, drainage area: 13.1 mi²), the mean annual runoff for Camp Creek during the pre-logging period is 4,120 acre-feet or 5.9 inches. A major portion of the annual runoff is derived from snowmelt. Streamflow usually begins to rise in April, reaches its peak magnitude from mid-May to early June, and then begins to recede to low flow levels in August and September. Annual maximum peak flows mainly result from snowmelt, with or without rainfall. The estimated 25-year return period maximum daily and instantaneous peak flows, $(q_{pd})_{25}$ and $(q_{pi})_{25}$, are 8 and 10 cfs/mi² respectively. Although annual minimum low flows can occur in the winter and early spring, it is the low flows in the summer months of August and September that are most important to the downstream water users for irrigation and

domestic purposes. The 25-year return period minimum 7-day average flow during the summer months is estimated to be 0.4 cfs or 0.03 cfs/mi². Other hydrometeorological characteristics of the Camp Creek watershed are summarized in the attached Hydrologic Inventory Form (Appendix I).

3. HYDROLOGIC EFFECTS OF LOGGING

As pointed out earlier, the total logged area from 1977 to July 1979 accounted for approximately 13 percent of the Camp Creek watershed. However, the salvage logging within the watershed is an on-going activity. According to the B.C. Forests Ministry, the logging company operating in this watershed (Gorman Brothers Ltd. of West Bank, B.C.), is short of timber and is planning to harvest all the areas that are affected by the mountain pine beetle. Therefore, it is very likely that the hydrologic effects of salvage logging in the watershed with respect to water quantity (water yield) and flow regime no matter how small in the initial stage may eventually build up over time to reach a significant magnitude as the scale and extent of logged areas increase. This could be particularly true when we consider the fact that the regrowth on most logged areas, especially in the high elevation zone, is very slow under the climatic constraints in the B.C. interior. The present B.C. Forests Ministry practice is first to rely on natural reproduction on all cut blocks, and then to check on the success of regeneration in the third year following logging. If a logged area is not satisfactorily stocked in terms of silvicultural objectives, a decision to plant is then made. Since it normally takes two years to grow useable seedlings, planting can only take place at least five years after logging. This practice, plus the unfavourable climatic conditions in interior B.C. for rapid vegetation regrowth mentioned previously, leads to a very slow overall vegetation recovery rate, particularly in terms of achieving a satisfactorily favourable level of forest influence on snow accumulation and melt as well as streamflow regime.

3.1 Erosion And Water Quality

With the exception of a small portion of the B.C. Hydro power-line right-of-way clearcut, the logged areas within the Camp Creek watershed are generally confined to fairly gentle and moderate terrain and, according to present B.C. Forest Ministry practices, logged areas with more than one-third exposed mineral soil are or will be seeded with grasses. Based on field observations made in August, 1979, no significant erosion problems are evident on logged areas. This field check also indicated that the logging roads have been adequately designed and constructed with suitable drainage facilities as there are no significant failures in road cuts or fills. Another field trip made in September 1980 in general confirms the above observations. It appears reasonable to assume that the degree and extent of ground disturbance associated with the salvage logging as presently evident in the Camp Creek watershed is not very likely to cause significant erosion and thus adversely affect the streamflow water quality through increased stream sedimentation.

3.2 Water Quantity And Flow Regime

In this and the following sub-sections, attempts are made to assess, by using the USFS water yield increase analysis procedure, the potential changes in annual water yield and flow regime (monthly flow distribution) of Camp Creek as a result of (1) past watershed salvage logging from 1977 to July 1979, ie., 1977-79 logging, and (2) additional salvage logging proposed for 1979-81.

3.2.1 Annual Water Yield

Water yield increases after watershed forest removal occur mainly as a result of (1) a reduction in evapotranspiration (interception and transpiration) losses, (2) an increase in wind turbulence that results in the redistribution of snow and greater local snow accumulation, and (3) more efficient conversion of the snowpack to streamflow. The water yield increase analysis procedure used by the USFS in Idaho and Montana (Isaacson, 1977; Russell, 1971) essentially calculates the annual water yield increase (AWYI) for each equivalent clearcut area (ECA) for various elevation zones on a small sub-drainage basis as follows:

$$AWYI = ECA \times K \times R$$

The value of ECA, in acres, is based on information obtained for each cut block on what and when ground cover changes took place and the actual extent of subsequent vegetation recovery. The water yield increase factor K expressed as a percentage increase is determined as a function of elevation as well as the form of precipitation. The runoff factor R expressed as depth in feet can be determined from regional runoff-elevation or precipitation-elevation relationships.

In order to apply the USFS procedure originally developed for Idaho and Montana to the Camp Creek watershed, the following explanations and assumptions have to be made.

1. Because of its small size (13 mi²), the layout of its drainage system and the distribution of logged areas (Figure 2), the Camp Creek watershed is not further divided into sub-drainages.
2. All the timber removal in the watershed is considered to be clearcut.
3. Due to the lack of detailed forest ecosystem maps required for developing suitable hydrologic recovery classes plus the fact that essentially reforestation for most logged areas has not yet started, all logged areas (1977-79, 1979-81) are assumed to be in the same hydrologic "condition" as in the first year following clearcutting, i.e., still at their maximum level of capability, 100% of ECA, for causing hydrological changes in terms of snow accumulation and melt. This assumption is expected to be one of the major sources of error in the results.
4. As there are no applicable data in the study region on water yield changes following watershed forest removal, the values of the on-site water yield increase factor K for various elevation zones in the Camp Creek watershed are simply adopted from Isaacson(1977) and Russell (1971) without any modification. This is expected to be the other source of error in the results.

A runoff-elevation relationship is required to provide runoff R values for various elevation zones in the Camp Creek watershed.

For this study, a regional runoff-elevation relationship is first developed using mean annual water yield and median elevation values for 13 watersheds located south of 50° latitude in the Okanagan Valley. The median watershed elevation values were either computed from topographic maps or obtained from Reksten (1974). The estimates of runoff values for various elevation zones obtained from this relationship were then adjusted to obtain a total annual water yield value that would most closely match the recorded value for Camp Creek (Appendix 2).

The calculations and estimates for potential mean annual water yield increase after the 1977-79 logging are presented in Table 2. This estimated mean annual water yield increase for Camp Creek is 152 acre-feet or a 3.5 percent increase over that under natural forest cover conditions. Similarly, the calculations and estimates for potential mean annual water yield increase after the completion of scheduled additional logging in 1981 are presented in Table 3. An increase of 284 acre-feet or 6.6 percent in mean annual water yield may be expected. An independent check on the validity of these results is not possible due to the lack of a nearby, unlogged control watershed that has concurrent streamflow data during the pre- and post-logging periods. Therefore, speculation on the probable magnitude of water yield increases as a result of future salvage logging has to be based on these results. If the rate and elevation distribution of future logging over the five years after 1981 is the same as the 1977-81 period, an increase of approximately 568 acre-feet, or 13.2 percent in annual

water yield might be expected after 1986. However, the vegetation recovery on some of the 1977-81 logged areas at that time will reduce the magnitude of this estimated increase. In most cases, the amount of mean annual water yield increase in the future would depend heavily on the actual rate of logging, its elevation distribution and the degree of vegetation regrowth on the earlier logged areas.

3.2.2 Flow Regime

The USFS water yield increase analysis procedure (Isaacson, 1977) permits the assessment of only two aspects of the flow regime: monthly flow distribution and the timing and magnitude of the maximum monthly flow. For these two aspects of flow regime calculations, tables of monthly percentage distribution of the mean annual water yield increase as a function of the elevation and aspect of a given ECA unit prepared by Isaacson (1977) for northern Idaho are used (Appendix 3). These tables show that the estimated monthly distribution of the mean annual water yield increase varies from March to August in response to changes in snowmelt rates and reduction in evapotranspiration losses as a result of forest removal. There are no locally available data which can be used to judge the applicability of those estimated increases to the Camp Creek watershed. This must be kept in mind when assessing the reliability of the final results.

The monthly distribution for mean annual water yield increase is mainly determined on the basis of the natural diversity in snow accumulation and melt that exists by virtue of differences in elevation, slope-aspect and vegetation cover. An increase in elevation at a given latitude is associated with an increase in snow accumulation, a delay in

snowmelt timing, and an increase in average melt rate over the snowmelt period. Slope-aspect influences snow accumulation and melt through its influence on radiation input and exposure to winds. The timing of initial and maximum snowmelt is earlier on the south aspect than on the north. Such differences are greatest at low elevation and decrease with increasing elevation. The results of experiments in the U.S.A. and Canada indicate that on all aspects and elevations, snowmelt in clearcut openings usually occurs earlier and at a rate higher than in the uncut forest. However, the higher melt rate for the opening is partially offset by the higher snow accumulation, and consequently the timing of snow disappearance from the opening could remain the same as for the original uncut forest. In British Columbia where the canopy openings created by harvesting are normally much larger (>40 acres) than those for experiments (<20 acres), rapid snowmelt due to exposure may result in much earlier snowpack disappearance than in the uncut forest.

The results of the monthly flow increase calculation (Appendix 4) for Camp Creek as a result of the 1977-79 salvage logging are presented in Table 4 and Figure 4. May, the month in which the highest monthly flow occurred before logging, has the highest flow increase in acre feet (62). April a low runoff month, has the highest percentage increase (14.8%) with March being the next highest (13.9%). The month of August has a mere 1.4 acre-feet or 0.8 percent increase in flow. This is partly due to the concentration of 1977-79 logging in the low elevation zones below 4,500 feet. For example, 24% of the area in the 3,500 - 4,500

foot elevation zone had been logged compared to only 7.8% of the area logged in the 4,500 - 5,000 foot zone during the 1977-79 salvage logging. As a result of increased logging above 4,000 feet from 1979 to 1981 (Table 3), most percentage monthly flow increases are shown to be more than double those resulting from 1977-79 logging (Table 5). The calculation of monthly flow increases as a result of 1977-81 logging is illustrated in Appendix 5 and Figure 5. If the majority of logging after 1981 is concentrated above 4,500 feet, the flow regime changes would respond accordingly with the possibility that the highest percentage flow increase would occur in May or June.

4. DISCUSSION

Because it was necessary to make certain assumptions and use curves and values developed by Isaacson (1977) and Russell (1971) without modification, the analysis as presented in this report is somewhat oversimplified. The factors and processes involved in determining the amount and timing of water yield changes following forest removal are very complex. The results of this study are intended to be used only as a first quantitative approximation.

An evaluation of the application of the USFS procedure to B.C. by Hetherington (1977) indicates that with adequate input data and proper interpretation of results, the water yield increase analysis procedure as proposed constitutes a valuable, practical tool for assessing the potential effects of forest harvesting on water yield. However, the available input data are far from adequate at the present time for most watersheds in B.C. The scarcity of locally available data on the impact of logging on water flows prevents a critical assessment of the analysis procedure as it applies to watersheds in B.C. This, in turn, makes the proper interpretation of the results a very difficult task at present.

Available streamflow data from hydrometric stations in the region of the Camp Creek watershed have made it possible to develop an adequate elevation-runoff relationship required for water yield increase calculations.

However, the lack of channel stability data as proposed by Pfankuch (1975) prevents a calculation of allowable annual cut for the study watershed. The assignment of hydrologic recovery curves to various cover types or ecosystem types, although not attempted in this study due to the lack of data, should definitely be included in future studies when more data and local research results become available.

Two other areas of concern which could be incorporated into the procedure with further research and development are the prediction of changes in maximum daily and instantaneous peak flows as well as changes in late summer low flows. The success of including these two aspects in the analysis procedure will of course depend on the availability of available input data and appropriate research results.

Because the potentially detrimental impact of forest harvesting on late summer low flows is of major concern to Trout Creek (and Okanagan Valley) water users, a brief discussion on this subject is appropriate.

Studies conducted in areas where precipitation is mainly in the form of rain indicate that forest removal, particularly from deep soil sites, reduces evapotranspiration, thereby increasing annual water yield and low summer flows. However, none of these studies involved serious ground disturbance to an extent that resulted in a significant reduction in soil infiltration capacity over the watershed. If the logging-induced infiltration reduction over the watershed is more than the saving in evapotranspiration losses associated with forest removal, there is a good chance that summer low flows may decrease despite an increase

in annual water yield. This would not appear to be an important factor in causing summer low flow reduction in the Camp Creek watershed according to our field observations. However, in areas like the Camp Creek watershed where streams are primarily fed by snowmelt, there is another possible cause of reduced summer low flows following logging. This arises when forest removal causes the snowpack in high elevation zones, considered to be the major source areas for summer low flows, to disappear completely at a much earlier date than under the original forest cover condition. In this case, although the soil moisture deficit under the forested condition may be greater due to high evapotranspiration losses, the reduced evapotranspiration losses following tree removal may be overridden by the lack of snowmelt contribution late in the summer. On the other hand (in the late summer months) if the accumulated soil moisture increase due to decreased evapotranspiration after forest removal is greater than the amount of reduction in snowmelt contribution due to earlier snowpack disappearance in the high elevation area, a certain increase in late summer low flows may be expected. Despite the great uncertainties involved in determining the direction (increase or decrease) and magnitude of logging-caused low summer flow changes for Camp Creek, it is hydrologically important for any forest harvesting operation to avoid significant ground disturbance and to minimize the detrimental impact of earlier snowpack disappearance in the high elevation areas of the watershed.

5. CONCLUSIONS

The application of the USFS water yield increase analysis procedure to assess streamflow changes after salvage logging in the Camp Creek watershed involves making reasonable assumptions and using available streamflow data to develop an adequate elevation-runoff relationship. The results of this analysis indicate that small percentage increases in mean annual water yield and monthly flows from March to August may be expected for Camp Creek as a result of the first three years (1977-79) of salvage logging. Following the completion of scheduled additional logging in 1981, the percentage increases in both mean annual water yield and monthly flows are expected to be more than double those resulting from the 1977-79 logging. The streamflow changes may eventually increase over time to reach a scale of significance to water management operations as the extent of salvage logging increases in response to the expansion of mountain pine beetle - attacked areas in the future. Field observations suggest that the present degree and extent of ground disturbance in the salvage-logged areas is not likely to cause significant erosion and stream sedimentation problems. When quantitative stream channel stability data for Camp Creek become available in the future, it would be possible to calculate the allowable annual cut for the watershed.

It appears that the USFS water yield increase analysis procedure in its present form may be utilized as a useful operational tool in assessing the impact of logging on some streamflow characteristics for

watersheds with adequate input data. The usefulness of this analysis procedure for application in B.C. can be assured and greatly enhanced if (1) it is modified to allow the assessment of the impact of logging on late summer low flow and daily peak flow, and (2) a well-designed province-wide data collection program is implemented to provide the required input data.
